Traffic and Quality Characterization of Scalable Encoded Video: A Large-Scale Trace-Based Study
Part 3: Statistical Analysis of Temporal Scalable Encoded Video

Abstract

In this part we analyze the nearly 110 hours of temporal scalable encoded video in our video trace library. We study the traffic characteristics of the base layer consisting of I and P frames and the enhancement layer consisting of B frames. We also study the video quality provided by the base layer as well as the aggregate (base + enhancement layer) stream. For the encodings without rate control, the base layer is equivalent to extracting the I and P frames out of a single layer encoding, while the enhancement layer is equivalent to extracting the B frames out of the single layer stream. Our statistical analysis provides insights into these layer streams. Our encodings with rate control have a rate-controlled base layer, while the corresponding enhancement layer is encoded without rate control. These encodings are well suited for simulating the widely advocated networking scenario with a nearly constant bit rate base layer and a variable bit rate enhancement layer.

1 Introduction

In this part we conduct a statistical analysis of the video traffic and the video quality for the temporal scalable encoded video. This statistical analysis is based on the terse traces of the base layer and the corresponding enhancement layer. Recall from Part 1 that the terse traces

give the frame sizes of the individual layers. In addition, the terse base layer trace gives the the qualities (PSNR values) of the luminance component of the base layer stream. The terse enhancement layer trace gives the improvement in the PSNR of the luminance component achieved by the enhancement layer.

2 Analysis of Video Traffic

In this section we analyze the frame sizes (traffic) of the temporal scalable encoded videos. We first study the statistical characteristics of the base layer traffic, then the enhancement layer traffic, and finally the correlations between base layer and enhancement layer traffic.

2.1 Base Layer Traffic

Recall that in the considered Type 1 temporal scalable encodings, the I and P frames constitute the base layer and the B frames constitute the enhancement layer. With the IBBPBBPBBPBBIBB... GoP structure, the frame sizes X^b_{3k+1} and X^b_{3k+2}, $k = 0, \ldots, N/3-1$, are zero (as these correspond to "gaps" in the base layer frame sequences). We give the compression ratios, the mean frame sizes ($\bar{X}^b$), the coefficients of variation (CoV^b_X), and the peak-to-mean ratios ($X^b_{\max}/\bar{X}^b$) in Table 1, along with the mean bit rates ($\bar{X}^b/T$), and the peak bit rate ($X^b_{\max}/T$). We define the compression ratio for the base layer as the ratio of the total file size of the uncompressed (YUV) video to the file size of the base layer.

We note by comparing Table 1 with Table 1 in Part 2 that the compression ratios of the temporal base layer without rate control are roughly two to three times larger than the compression ratios of the single layer encodings. (Equivalently, the $\bar{X}^b$ is roughly one third to one half of the $\bar{X}$ in Part 2.) This is reasonable since for every three frames in the single layer encoding there is one frame in the temporal base layer encodings, with the base layer containing the typically large I and P frames.

For the encodings with rate control we observe that the encoder meets all of the specified target bit rates with high accuracy. This is in contrast to the single layer encoding where the encoder was not able to meet the 64 kbps target bit rate. When encoding the base layer, the encoder has to "squeeze" fewer frames into the assigned target bit rate, 4 frames per GoP in the temporal base layer versus 12 frames for the single layer encoding. All of the low quality base layer encodings (which use a quantization parameter of 30) have a mean bit rate below 64 kbps; in fact, the mean bit rates are all below 50 kbps. As a consequence the encoder has "room" to adjust the quantization parameters in their valid range (up to 31) to meet the target bit rate.

For the encodings without rate control we observe again a significant peak in the variability (both in terms of CoV_X^b and $X_{\max}^b/\bar{X}^b$) for encodings at the medium quality level. In addition, the high quality base layer has somewhat smaller variability than the low quality base layer.

We observe that the temporal base layer traffic is significantly more variable than the comparable single layer traffic. The $X^b_{\max}/\bar{X}^b$ is roughly 1.5 to 2 times the $X_{\max}/\bar{X}$. This large variability is due to the fact that the frames missing in the base layer are counted as zeros in the frame size analysis, i.e., the frame size analysis considers a scenario where each frame is transmitted during its frame period of 33 msec and nothing is transmitted during the periods of the skipped frames. (A scenario where the transmission of a base layer frame is distributed equally over the 100 msec between successive base layer frames is considered in Table 2 below.) Note, however, that the temporal base layer with a target bit rate of 64 kbps is highly variable. The extremely high peak–to–mean ratios are due to a few extremely large frames. The coefficient of variation for the rate-controlled base layer tends to decrease as the target bit rate increases. Overall, the coefficients of variation for the rate-controlled base layers are comparable to the coefficients of variation for the base layers without rate control.

In addition to X_n^b, $n = 0, \ldots, N-1$, we consider a smoothed base layer trace O_n^b, $n = 0, \ldots, N-1$, defined as follows. $O_{3k}^b = O_{3k+1}^b = O_{3k+2}^b = X_{3k}^b/3$ for $k = 0, \ldots, N/3 - 1$. (Note that analyzing O_n^b is equivalent to analyzing $X_n^{b(3)}$, the aggregated base layer trace with aggregation level $a = 3$.) The coefficient of variation $CoV_X^{b(3)}$, and the peak-to-mean ratio $X_{\max}^{b(3)}/\bar{X}^b$ are given in Table 2, along with the peak bit rate $X_{\max}^{b,(3)}/T$ of the smoothed trace.

Table 2: Overview of frame statistics of the smoothed base layer of temporal scalable encoded video

Aggregating three base layer frames (i.e., an I or P frame and two missing frames of size zero) or equivalently spreading the transmission of each base layer frame over three frame periods roughly reduces the standard deviation by a factor of three while leaving the mean unchanged. Thus, the coefficient of variation is reduced by roughly a factor of three. The peak bit rate and the peak-to-mean ratio of the $X_n^{b(3)}$ trace are exactly three times smaller compared to the unsmoothed X_n^b.

Comparing now the $X_n^{b(3)}$ traces with the corresponding single layer traces, we observe that the $X_n^{b(3)}$ trace is significantly less variable, with the $X_{\max}^{b(3)}/\bar{X}^b$ being typically one half to two thirds of the $X_{\max}/\bar{X}$. In other words the temporal base layer stream, consisting of I and P frames, is significantly less variable than the complete video stream. This indicates that the I and P frames are relatively less variable in size compared to the B frames. In other words, the B frames tend to be more variable in size compared to I and P frames. This is intuitive, as B frames can cover the entire range from being completely intra-coded (e.g., when the scene change occurs at that frame) to being completely inter-coded. In addition, the wide variety of motion vector types used in the predictive inter-coding contributes to the size variations. The variability of the B frames is studied in more detail in the section on the enhancement layer traffic. The observation of the base layer being less variable holds even stronger for the rate-controlled encodings with $X_{\max}^{b(3)}/\bar{X}^b$ typically being one third or less of the corresponding $X_{\max}/\bar{X}$. We also observe that the rate-controlled base layer has smaller coefficients of variation than the base layers without rate control.

Table 3 gives the mean *GoP* size ($\bar{Y}^b$), the coefficient of variation of the GoP sizes (CoV_Y^b), and the peak-to-mean ratio ($Y_{\max}^b/\bar{Y}^b$) of the GoP sizes, as well as the peak bit rate ($Y_{\max}^b/(GT)$) of the GoP trace. Note that at the GoP level there is no difference between the unsmoothed frame size trace X_n and the smoothed frame size trace O_n, i.e., both X_n, and O_n result in the same Y_m sequence.

For the encodings without rate control we observe again a peak in the traffic variability at the medium quality level. We also observe again that the temporal base layer GoP traffic is less variable than the corresponding single layer traffic. Also, the rate-controlled base layers are significantly less variable than the base layers without rate control. The coefficients of variation

CoV_X^b are good indicators of the general smoothness of the rate-controlled base layers at the GoP aggregation level. For the 256 kbps base layer the CoV_X^b are roughly an order of magnitude smaller than for the encodings without rate control. The CoV_X^b for the 128 kbps and 64 kbps are larger than for the 256 kbps base layer; however, the 128 kbps and 64 kbps CoV_X^b's are still significantly smaller than for the base layer without rate control. The 64 kbps base layers tend to have peak-to-mean GoP size ratios that are on the order of the ratios for the encodings without rate control. This is due to some extremely large GoPs, which are however rare.

The peak rates of the 128 kbps and 256 kbps base layers at the GoP aggregation level are quite close to the mean bit rate. The peak rates of the 128 kbps base layers are typically less than 200 kbps and the peak rates of the 256 kbps base layers are typically less than 300 kbps. This enables the transport of the base layer with rate control over reliable constant bit rate network "pipes" — provisioned, for instance, using the guaranteed service paradigm [1].

Note, that even these rate-controlled encodings at the GoP aggregation level require some amount of over-provisioning since the peak rates are larger than the mean bit rates. As illustrated in the following figures, (see in particular Figure 3) excursions above (and below) the mean bit rate are typically short-lived. Therefore, any of the common smoothing algorithms (e.g., [2], [3], [4], [5]) should be able to reduce the peak rates of the GoP streams to rates very close to the mean bit rate with a moderately-sized smoothing buffer. In addition, note that the TM5 rate control employed in our encodings is a basic rate control scheme which is standardized and widely used. More sophisticated and refined rate control schemes (see for example [6], [7], [8], [9], [10]) may further reduce the variability of the traffic (and also achieve a better rate-distortion performance).

Figure 1 gives the (unsmoothed) frame size X_n^b (in bytes) as a function of the frame number n. For the encodings with rate control we observe again the pronounced variability of the frame sizes. Note that the outlines of the upper borders of the shaded areas are strikingly similar to the corresponding outlines in Figure 1 of Part 2.

As we discuss in detail later in this part, the temporal base layer is approximately equivalent to extracting the I and P frames out of a single layer encoding. The plots in Figure 1 may serve as a visual "proof"; the large I and P frames, which span the upper borders of the shaded areas in the plots, are the same as in Figure 1 of Part 2.

The smaller B frames, which span the lower border of the shaded area in the plots of Figure 2 of Part 2 are replaced by zeros in the base layer size traces. Thus the shading extends to the x-axis in the corresponding regions of Figure 1. For the encodings with rate control we observe that the base layers appear to have fewer "spikes" of extremely large frames compared to the corresponding single layer encodings.

Figure 2 gives the smoothed frames size $X_n^{b(3)}$ (in bytes) as a function of the frame number n. These plots complement the statistics given in Table 2 for the smoothed base layer traces. While the smoothing over 3 frames has significantly reduced the variability by eliminating the "zeros" in the traces, there is still significant variability present, even for the rate-controlled sequences.

Figure 3 gives the GoP size Y_m^b (in bytes) as a function of the GoP number m. For encodings without rate control we observe the traffic variations that are typical for open-loop encodings. The GoP sizes of the encodings with rate control, on the other hand, are centered around the target GoP size, with only occasional excursions. Also, as already noted for Table 3, the GoP size traces of the base layer encodings have smaller outlines than the GoP sizes of the single layer encodings. Figure 3 underscores that the GoP size traffic of the temporal base layer is less variable.

In the following analysis we focus on the smoothed frame size trace $O_n^b,\ n = 0, \ldots, N-1$; for conciseness we analyze the equivalent trace $X_n^{b(3)},\ n = 0, \ldots, N/3 - 1$.

Figure 4 gives the histograms of the frame sizes $X_n^{b(3)}$. Note that these histograms are quite similar to the histograms obtained by scaling the frame sizes in the single layer histograms in Figure 2 of Part 2 by a factor of three. The most significant difference is that the tails (probabilities for layer frame sizes) are amplified in the histograms here. This reflects the fact that the large I and P frames are in the base layer. Note that the encodings with rate control have two "humps", which are more pronounced here than for the single layer encodings.

Figure 5 gives the histograms of the GoP sizes Y_m. Most striking is that the GoP size histograms for the encodings with rate control are very narrow.

Figure 6 gives the autocorrelation coefficient $\rho^b_{X^{(3)}}(k)$ of the frame size sequence $X_n^{b(3)}$, $n = 0, \ldots, N/3 - 1$, as a function of the lag k (in frames). For the encodings without rate control we observe that the three small spikes between I frames which are present in the single layer, are absent in temporal base layer.

Figure 7 gives the autocorrelation coefficient $\rho^b_Y(k)$ of the GoP size sequence Y^b_m, $m = 0, \ldots, N/G - 1$, as a function of the lag k (in GoPs). We observe that the GoP autocorrelation functions for the base layer encodings without rate control are very similar to the autocorrelation functions of the single layer encodings. We also observe that the autocorrelation functions for the encodings with rate control drop off very quickly to zero and then either hover around zero with very small amplitudes (128 kbps and 256 kbps base layers) or somewhat larger amplitudes (64 kbps). The 64 kbps and 128 kbps base layer autocorrelation functions, in particular, are significantly closer to zero than the autocorrelation functions of the corresponding single layer encodings. This appears to indicate once more the better performance of the TM5 rate control for the base layers.

Table 4 gives the Hurst parameter obtained with the R/S heuristics and the periodogram for X^b_n, $n = 0, \ldots, N - 1$, as a function of the aggregation level a. Comparing Table 4 with the Table 3 of Part 2, we observe that the Hurst parameter estimates of the data generated by the two encoding types — single layer and temporal base layer — are almost the same for the different aggregation levels for encodings without rate control.

For the encodings with rate control, the Hurst parameter estimates are again below 0.5 for most videos and bit rates, making the estimates invalid. Only the 64 kbps *Alladin* and *Lecture–Reisslein* encodings have Hurst parameter estimates above 0.5, which, however, drop off to close to 0.5 for large aggregation levels. Thus, there is not a strong indication that these traces have long range dependence properties.

Table 4: Hurst parameters estimated from pox diagram of R/S and program as a function of the aggregation level a.

Figures 8, 9, and 10 give the variance-time plots, the pox plots of R/S (for $a = 12$), and the periodograms (for $a = 12$). Figure 11 gives the logscale diagrams. Figures 12 and 13 give the multiscale diagrams and the linear multiscale diagrams. From Table 5 we observe that in

most cases the logscale H estimate closely matches that of the single layer. However, some video sequences show a considerable difference in the H estimate than what was observed for the single layer encodings. For example, the high quality *Star Wars IV* encoding has an H estimate of 0.8 for the single layer, whereas the temporal base layer has 1.017. The logscale diagram H estimates are negative for the 64 kbps target bit rate base layer encodings because of the effectiveness of rate control at 64 kbps. In single layer encodings where we do not find rate control at 64 kbps to be effective, we observe large values of H (typically larger than 0.5) estimate using logscale technique.

The Hurst parameter estimates obtained from the variance test analysis have roughly the same value for both the single layer and temporal base layer encodings. As was observed earlier, the variance test analysis gives the lowest estimate of the Hurst parameter compared to the other methods.

From Figure 11 we observe that the logscale plots for temporal base layer encodings without rate control exhibit the same properties as were observed in the logscale plots for the single layer encodings in Figure 9 of Part 2. As was observed for the single layer encodings, we again observe a "knee" around scale $j = 4$ or $j = 5$. Since we have only I and P frames in the temporal base layer encodings, the similarities of the logscale plots here with the plots in Figure 9 of Part 2 appear to indicate that the scaling properties of the I and P frame sequence are the same as for the full I, P and B frame sequence.

2.2 Enhancement Layer Traffic

Note that with the GoP pattern IBBPBBPBBPBBIBB..., I and P frames make up the base layer and B frames make up the enhancement layer; the enhancement layer frame sizes, X^e_{3k}, are zero, and the enhancement layer frame sizes, X^e_{3k+1} and X^e_{3k+2}, $k = 0, \ldots, N/3 - 1$ are nonzero.

Table 7 gives the mean frame sizes ($\bar{X}^e$), the coefficients of variation (CoV^e_X), and the peak-to-mean ratios ($X^e_{\max}/\bar{X}^e$) of the enhancement layer frame sizes along with the mean bit rate ($\bar{X}^e/T$) and the peak bit rate ($X^e_{\max}/T$).

Table 7: Overview of frame statistics of the enhancement layer of temporal scalable encoded video

		Frame Size			Bit Rate

We consider two smoothed versions of the enhancement layer trace. We define the two-frame smoothed enhancement layer trace $O_n^e,\ n = 0, \ldots, N-1$, as follows. $O_{3k}^e = O_{3k+1}^e = X_{3k+1}^e/2$ and $O_{3k+2}^e = X_{3k+2}^e$ for $k = 0, \ldots, N/3 - 1$. We define the three-frame smoothed enhancement layer trace $P_n^e,\ n = 0, \ldots, N-1$, as $P_{3k}^e = P_{3k+1}^e = P_{3k+2}^e = (X_{3k+1}^e + X_{3k+1}^e)/3$ for $k = 0, \ldots, N/3-1$. (Note that the statistical analysis of $P_n^e,\ n = 0, \ldots, N-1$, is equivalent to the statistical analysis of the aggregated enhancement layer trace with aggregation level $a = 3$, i.e., $X_n^{e(3)},\ n = 0, \ldots, N/3 - 1$.)

Table 8 gives the coefficients of variation (CoV_O^e and CoV_P^p), the peak-to-mean ratios ($O_{\max}^e/\bar{X}^e$ and $P_{\max}^e/\bar{X}^e$) along with the peak bit rates ($O_{\max}^e/T$ and $P_{\max}^e/T$) of the smoothed traces.

Table 8: Overview of frame statistics of the smoothed enhancement layer of temporal scalable encoded video

The main features of the temporal enhancement layer traffic without rate control are summarized as follows:

- A very pronounced "hump" in the variability at the medium quality level.
- A relatively large variability compared to the single layer encodings, which, as noted above, is due to the wide range of sizes for the B frames.

The main features of the temporal enhancement layer traffic corresponding to the rate-controlled base layer are:

- The mean bit rate of the enhancement layer decreases as the target bit rate of the base layer increases. This is clearly expected as the higher bit rate base layer contains a more accurate encoding of the video, leaving less video information to be encoded in the enhancement layer.
- A somewhat higher variability compared to the medium quality single layer encoding (which uses the same quantization parameters as the enhancement layer of the rate-controlled base layer.).
- A slight tendency of the enhancement layer traffic to become more variable as the base layer target bit rate increases.
- About the same level of variability as the enhancement layer at the medium quality level without rate control.

Figure 14 gives the (unsmoothed) frame size X_n^e (in bytes) as a function of the frame number n. Figure 15 gives the GoP size Y_m^e (in bytes) as a function of the GoP number m. The high variability of the enhancement layer traffic is also reflected in these frame size and GoP size plots. Notice in particular the high variability of the enhancement layer as the rate-controlled encodings as well as the similarities between the *Jurassic Park I* enhancement layers with and without rate control for the base layer.

In the following analysis we focus on the 3-frame smoothed frame size trace $P_n^e,\ n = 0, \ldots, N-1$; for conciseness, we analyze the statistically equivalent trace $X_n^{e(3)},\ n = 0, \ldots, N/3-1$.

Figure 16 gives the histograms of the frame sizes $X_n^{e(3)}$. Note that the histograms for the enhancement layers that correspond to the rate-controlled base layers are cut off at a frame size of 3000 bytes for ease of comparison and thus, do not include the rare extremely large frames.

Figure 18 gives the autocorrelation coefficient $\rho^e_{X^{(3)}}(k)$ of the frame size sequence $X_n^{e(3)},\ n = 0, \ldots, N/3-1$, as a function of the lag k (in frames). For almost all of the encodings without rate control we observe periodic oscillations of the autocorrelation function, which are especially pronounced for the low quality encodings, with a period of 12 frames (i.e., one GoP). The explanation of this phenomenon is as follows. B frames are generally encoded with respect to the I or P frame that has the smallest difference (on a macro-block basis). For the last 2 two B frames in a GoP, the following I frame is typically chosen as the reference. This I frame typically gives smaller differences because the other alternative — the P frame preceding the last two B frames in the GoP — tends to accumulate forward prediction error throughout the GoP. Encoding the last two B frames with respect to the next I frame, however, requires a new set of (absolute) motion vectors, whereas the preceding B frames in the GoP are typically encoded with respect to the preceeding I and P frames using relative (differential) motion vectors. Since the absolute motion vector require more encoding bits than the differential motion vectors, the last two B frames in the GoP are typically lower, resulting in the periodic spikes in the depicted autocorrelation function.

The underlying trend of the autocorrelation function becomes apparent in Figure 19, which gives the autocorrelation coefficient $(\rho^e_Y(k))$ of the GoP size sequence $Y_m^e,\ m = 0, \ldots, N/G-1$, as a function of the lag k (in GoPs). The autocorrelations decay quite slowly and remain at a level of 0.1 for lags up to 120 GoPs (i.e., 48 seconds) for *Star Wars IV* and remain at even higher levels for *Silence of the Lambs*. This decay occurs much more rapidly for the *Jurassic Park I* sequence.

Table 10 gives the Hurst parameter obtained with the R/S heuristics and the periodogram

for $X_n^e,\ n = 0, \ldots, N-1$, as a function of the aggregation level a.

Table 10: Hurst parameters estimated from pox diagram of R/S and periodogram as a function of the aggregation level a.

Figures 20, 21, and 22 give the variance-time plots, the pox plots of R/S (for $a = 12$), and the periodogram (for $a = 12$). Figure 23 gives the logscale diagrams. Figures 24 and 25 give the multiscale diagrams and the linear multiscale diagrams.

In summary, we observe from the scaling analysis that the enhancement layers of the encodings without rate control exhibit long range dependence and have scaling properties that are very similar to the corresponding single layer encodings without rate control. *Die Hard I* and *Jurassic Park I* again have the smallest degree of long range dependence. Again, there appears to be no clear trend in the Hurst parameter estimates for the different quality levels of a given video. In contrast to earlier results, the enhancement layers of the encodings with rate control now exhibit long range dependence, which is due to the enhancement layers being encoded with fixed quantization parameters, whereas the corresponding base layers are rate-controlled.

Notice from Figure 25d that the confidence intervals of $h_{0.5}$ and h_4 are separated by approximately 0.1, which gives some indication of multiscaling properties. Interestingly, this particular video traffic stream considered in Figure 25d is the only stream in our library that gives this indication of multiscaling.

2.3 Aggregated Traffic and Correlation between Base and Enhancement Layer Traffic

In this section we investigate the aggregate (base + enhancement layer) traffic and the correlation between the base layer and the enhancement layer traffic of temporal scalable encoded video. In this investigation we consider the smoothed base layer trace $X_n^{b(3)},\ n = 0, \ldots, N/3-1$, and the 3-frame smoothed enhancement layer trace $X_n^{e(3)},\ n = 0, \ldots, N/3-1$. We estimate the covariance between base layer and enhancement layer at the 3-frame aggregation level as

$$S_{be}^{(3)} = \frac{1}{N/3-1} \sum_{n=0}^{N/3-1} (X_n^{b(3)} - \bar{X}^b)(X_n^{e(3)} - \bar{X}^e), \tag{1}$$

and the base–enhancement layer correlation coefficient as

$$\rho_{be}^{(3)} = \frac{S_{be}^{(3)}}{S_{X^{(3)}}^b \cdot S_{X^{(3)}}^e}. \tag{2}$$

Similarly, we estimate the covariance between base layer and enhancement layer at the GoP level as

$$S_{be}^{(G)} = \frac{1}{N/G-1} \sum_{m=0}^{N/G-1} (Y_m^b - \bar{Y}^b)(Y_m^e - \bar{Y}^e), \tag{3}$$

and the corresponding correlation coefficient as

$$\rho_{be}^{(G)} = \frac{S_{be}^{(G)}}{S_Y^b \cdot S_Y^e}. \tag{4}$$

We also investigate the characteristics of the aggregate traffic at the frame time scale $X_n = X_n^b + X_n^e,\ n = 0, \ldots, N-1$, and the GoP time scale $Y_m = Y_m^b + Y_m^e,\ m = 0, \ldots, N/G-1$. The compression ratios, mean frame sizes ($\bar{X}$), the coefficients of variation (CoV_X), the peak-to-mean ratios ($X_{\max}/\bar{X}$), along with the bit rates and the base-enhancement layer correlation coefficients ($\rho_{be}^{(3)}$) are reported in Table 13. Table 14 gives the mean GoP sizes ($\bar{Y}$), the coefficients of variation (CoV_Y), the peak-to-mean ratios ($Y_{\max}/\bar{Y}$), along with the peak bit rates ($Y_{\max}/(GT)$) and the GoP level base-enhancement layer correlation coefficients (ρ_{be}^{G}).

For the encodings without rate control we observe that the frame level and GoP level statistics are approximately equal to the corresponding statistics of the single layer encodings studied in Part 2. For the temporal scalable encodings with rate control, on the other hand, the rate-controlled base layer and the open-loop encoded enhancement layer are aggregated. For the 64 kbps base layer encodings, the resulting aggregated traffic stream is at the frame level less variable than the 64 kbps single layer encodings (although this may be due to the failure of the TM5 rate control to meet this target bit rate for the single layer) but significantly more

variable than the medium and low quality level single layer encodings without rate control. For the 128 kbps and 256 kbps base layer encodings, the variability of the aggregate frame level traffic is roughly comparable to the variability of the low quality level single layer encodings.

Table 13: Overview of frame–level statistics of aggregated temporal scalable video traffic

3 Analysis of Video Quality

In this section we study the video quality of the base layer stream and the aggregate (base + enhancement layer) stream. This quality analysis focuses on the quality of the luminance component.

3.1 Base Layer Quality

We first consider the base layer. Recall that $Q_n^{b,Y}$, $n = 0, \ldots, N-1$, denotes the PSNR quality (in dB) of the luminance component in frame n. For convenience, we write Q_n^b for $Q_n^{b,Y}$, and M_n^b for the corresponding MSE quality, i.e., $M_n^b = p^2/(10^{(Q_n/10)})$.

Table 15 gives the average qualities ($\bar{Q}^b$), the coefficients of quality variation ($CoQV^b$ and $CoQV'^b$), and the quality ranges ($Q_{\min}^{\max,b}$) for the decoded base layer stream. The quality statistics are provided for the frame-level and the GoP-level.

Table 15: Overview of quality statistics of base layer of temporal scalable encoded video

		Frame Level				GoP level		
Enc. M.	Video	$\bar{Q}^b$	$CoQV^b$	$CoQV'^b$	$Q_{\min}^{\max,b}$	$CoQC^{(G),b}$	$CoQV'^{(G),b}$	$Q_{\min}^{\max,(G),b}$

For the encodings without rate control we observe that the average qualities of the base layer are significantly (5–10 dB) smaller than the average qualities of the corresponding single layer encodings (see Table 6 of Part 2). Also, the alternative coefficients of variation of the base layer are roughly one order of magnitude larger than for the single layer encodings. The quality range of the base layer is also significantly larger. Thus, we conclude that skipping the B frames reduces the video quality quite significantly with respect to the single layer encodings. In particular, the temporal base layer has significant variations in the displayed video quality

since only every third frame is decoded and is displayed in place of the missing frames in between. The reduction in quality with respect to the single layer encodings is not as severe for the rate-controlled sequences. There are two effects at work here. First, the base layer (i.e., the I and P frames) is allocated the full target bit rate in the temporal scalable encodings, whereas the target bit rate needs to accommodate all frame types (I, P as well as B frames) in the single layer encodings. Thus, in the temporal scalable encoder, more bits can be allocated to the I and P frames, i.e., these are encoded at a higher quality.

The second effect is again the skipping of the B frames, which reduces the quality of the displayed video. As we note by comparing the Table 13 here with Table 6 in Part 2, this second effect dominates, especially for the 64 kbps and 128 kbps base layer encodings.

Figure 26 gives the video frame qualities Q_n^b (in dB) as a function of the frame number n. These plots clearly illustrate the severe impact of the missing B frames on the video quality. This effect becomes especially apparent by comparing these plots here with the corresponding single layer plots in Figure 11 of Part 2.

Figure 27 gives the histogram of the frame qualities Q_n^b. Figure 28 gives the MSE autocorrelation coefficient $\rho_M(k)$ as a function of lag k (in frames). All of the $\rho_M(k)$ plots exhibit periodic spikes that are spaced 3 frames apart. These periodic spikes are due to the fact that every third frame is actually a decoded I or P frame — giving a relatively high PSNR — whereas the two frames in between are approximated by the preceding decoded frame, giving relatively low PSNR. From these plots and also the plots in Figure 29, which give the MSE autocorrelation coefficient $\rho_M^{(G)}(k)$ as a function of the lag k (in GoPs), we observe that the MSE autocorrelations of the base layer drop off relatively quickly to levels around 0.1 for lags of 100 GoPs. This is in contrast to the MSE autocorrelations of the single layer encodings, (see Figure 13 of Part 2) which drop off more slowly and remain at higher levels for large lags.

3.2 Quality of Aggregate Video Stream

We now proceed to study the quality of the aggregate stream. Recall that $Q_n^{e,Y},\ n = 0, \ldots, N-1$, denotes the improvement in the PSNR quality (in dB) of the luminance component in frame n, achieved by adding the enhancement layer. We denote $Q_n^{\text{agg}},\ n = 0, \ldots, N-1$, for the PSNR quality (in dB) of the luminance component in the decoded aggregate stream. By definition, $Q_n^{\text{agg}} = Q_n^b + Q_n^e,\ n = 0, \ldots, N-1$. We denote $M_n^{\text{agg}},\ n = 0, \ldots, N-1$, for the corresponding MSE quality.

Table 16 gives the average qualities ($\bar{Q}^{agg}$), the coefficients of quality variation ($CoQV^{agg}$), and the quality ranges ($Q_{\min}^{\max,agg}$) for the decoded base layer stream. The quality statistics are provided for the frame-level and the GoP-level.

Table 16: Overview of quality statistics of the aggregate stream of temporal scalable encoded video

		Frame Level				GoP level

For the encodings, without rate control we observe that the quality statistics of the aggregate streams match exactly the quality statistics of the corresponding single layer encodings.

For the encodings with rate control, we observe that the average quality increases by about 1.5–2 dB each time the base layer target bit rate is doubled from 64 kbps to 128 kbps and then from 128 kbps to 256 kbps. We also observe that the average PSNR qualities of the aggregate (base + enhancement layer) stream with a rate-controlled base layer are roughly 0.5–1.5 dB higher than the corresponding rate-controlled single layer streams.

Figure 30 gives the video frame qualities Q_n^{agg} (in dB) as a function of the frame number n. For the encodings without rate control the plots here match exactly the corresponding plots in Figure 11 of Part 2. For the encodings with rate control the plots here are very similar to the corresponding plots in Figure 11 of Part 2, the only apparent difference is that the plots here reach qualities that are just a few dB higher than in Figure 11 of Part 2. Similar observations hold for Figure 31 which gives the histogram of the frame qualities.

Figure 32 gives the MSE autocorrelation coefficient $\rho_M(k)$ as a function of lag k (in frames). Figure 33 gives the MSE autocorrelation coefficient $\rho_M^{(G)}(k)$ as a function of lag k (in GoPs). We observe that the frame MSE autocorrelation functions $\rho_M(k)$ have a pronounced GoP periodicity at the high and medium quality levels (without rate control). The frame MSE autocorrelation function $\rho_M(k)$ for the encodings with rate control exhibit a pronounced 3-frame periodicity. The GoP MSE autocorrelations are generally significant, but lower than for the corresponding single layer encodings.

4 Correlation between Frame Sizes and Qualities

Table 17 gives the correlation coefficients between the quality and the frame size, both for the base layer and the aggregate stream. Both the MSE quality-to-frame size correlation (ρ_{XM}) and the PSNR quality-to-frame size correlation (ρ_{XQ}) are provided, for the frame level and the GoP aggregation level.

We observe several interesting trends in the quality-traffic correlations. For instance, ρ_{XQ} at the frame level is positive throughout and decreases in magnitude as the quality level decreases. The corresponding $\rho_{XQ}^{(G)}$, on the other hand, are negative throughout, and tend to be close to -1, especially for the lower quality levels. Similar trends can be observed for the other scenarios given in Table 17.

Overall, we conclude that there are non-trivial behaviors of the traffic-quality correlations in long encodings. We plan to study these in detail in future work. In particular, we plan to study the traffic and quality in conjunction with the video content features to uncover the fundamental characteristics of the traffic-quality correlations and their implications for video encoding and network transport.

Figures 34 and 35 give scatter plots of the tuples $(X_n,\ Q_n)$ and $(X_n^{(12)},\ Q_n^{(12)})$, respectively.

Figure 36 gives the rate-distortion plots, i.e., the average video quality $(\bar{Q})$ as a function of the average frame size $(\bar{X})$. The plots are obtained from the five different quality level encodings of the videos.

5 Discussion

As we have observed in the preceding sections, for the encodings without rate control, aggregating the base and enhancement layers gives video streams that are equivalent to the corresponding single layer stream studied in Part 2. In extensive numerical investigations, not detailed here due to space constraints, we have also verified that extracting the I and P frames out of a single layer encoding is equivalent to the base layer of a temporal scalable encoding. Extracting the B frames out of a single layer encoding gives a stream equivalent to the enhancement layer of a temporal scalable encoding. This is to be expected as temporal scalable encoding adds essentially no overhead.

Note that the above holds only for the encodings without rate control (i.e., when the quantization parameters are fixed for the entire duration of a given video). If rate control is employed for the base layer encoding, the obtained base layer is very different from the I and P frame sequence of a single layer encoding — both if it is done with or without rate control. Similarly, the enhancement layer obtained from an actual temporal scalable encoding with a rate-controlled base layer is quite different from the B frame sequence of a single layer encoding, even though the enhancement layer of the temporal scalable encoding is coded with fixed quantization parameters. In particular, the higher the base layer (target) bit rate, the lower the average enhancement layer bit rate. This is intuitive since the more information is accommodated in the base layer, the smaller the amount of information left over for the enhancement layer.

6 Conclusion

Our traces of temporal scalable encoded videos with rate control for the base layer provide realistic traffic data for evaluating the widely advocated networking scenario with a (nearly) constant bit rate base layer and a variable bit rate enhancement layer. The widely used TM5 rate control mechanism, which we also employed in our encodings, tries to stabilize the bit rate at the GoP time scale (while the bit rate at the frame time scale is quite variable). We therefore recommend to employ our traces in scenarios were the video traffic is smoothed over the individual frames in a GoP (which incurs a delay of only about 0.4 sec) or using some other

smoothing algorithm.
